ABSTRACT The spillover phenomenon, which essentially involves transfer of H from a metal catalyst to a graphitic receptor, has been considered promising for efficient hydrogen storage. An open question about the spillover mechanism is how a H atom binds to graphene instead of forming the thermodynamically preferred H₂. Using ab initio calculations, we show that the catalyst saturation provides a way to the adsorption of hydrogen on the receptor by increasing the H chemical potential to a spillover favorable range. Although it is energetically unfavorable for the spillover to occur on a pristine graphene surface, presence of a phase of hydrogenated graphene facilitates the spillover by significantly improving the C—H binding. We show that thermodynamic spillover can occur, both from the free-standing and from the receptor-supported clusters. Further, the computed energy barrier of the motion of a H from the catalyst to the hydrogenated graphene is small (0.7 eV) and can be overcome at operational temperatures.

KEYWORDS: hydrogen storage · spillover · catalysis · graphene · ab initio thermodynamics

Hydrogen is a carrier of clean energy¹,² and can be easily generated from renewable sources. A cost-effective, safe, and efficient storage medium is the key to utilize its full potential. Among the various possibilities, the carbon-based adsorbents³–⁸ are recognized as strong candidates, where large surface area and lighter weight make the substantial volumetric and gravimetric content possible. Furthermore, the storage capacity of graphitic materials (e.g., nanotubes and fullerenes) can be significantly enhanced by decorating them with metal atoms⁹–¹⁴ which absorb multiple H₂ molecules via Kubas interaction.¹⁵ Although promising, the experimental efforts in synthesizing the metal-decorated nanotubes and fullerenes have not been successful so far. Additionally, the tendency of metal atoms to cluster¹⁶,¹⁷ leads to considerable reduction in potential storage capacity. In contrast, the metal cluster supported on graphitic materials acts as a catalyst and enhances the hydrogen uptake of substrates via spillover.¹⁸–²¹

The spillover process involves the transport of an active species (e.g., H) formed on a catalyst onto a receptor that does not sorb the species²² under the same conditions. Current growing interest in efficient storage of hydrogen brought this long-known phenomenon into the spotlight. The most widely used catalysts for spillover of H atoms on graphitic materials are Ni, Pd, Pt, and other transition metal atoms. Recently, several experiments have shown the enhancement of H₂ adsorption via spillover on activated carbons and MOF.¹⁹,²³–²⁵ Up to 4 wt % of adsorption has been reported for IRMOF-8 at 298 K and 10 MPa.²⁶ Furthermore, it is empirically established that the spillover can be enhanced by adding so-called bridges²⁴ between the catalyst and receptor. Although exact distribution and the binding sites of the H remain experimentally unspecified, it is reasonable to suggest that the best coverage of the H on graphitic substrates can be achieved when they are hydrogenated on both sides²⁷,²⁸ and spillover is considered as a possible path to achieving it. Thus, fully hydrogenated graphene would have stoichiometry CH, with 7.7 wt % of hydrogen²⁷–⁴⁰ meeting the DOE goals. Even though the spillover of the H on graphitic surfaces was observed decades ago,²² it is still not well-understood how a H binds to graphene when it seems energetically more favorable to stay on the catalyst or even to remain in a molecular H₂ form in the gas phase. To better understand the spillover mechanism, with the goal to optimize its kinetics, it is important to compare the relative energy states of the hydrogen in its (i) dihydrogen gas form, (ii) at the metal catalyst, and (iii) on the receptor substrate (Figure 1). The energy states available for H will depend on the degree of saturation or substrate coverage.
Figure 1. Left: Schematics of spillover process in real space. The inequality shows the range of chemical potential $\mu_H$ favorable for spillover. Right: model of spillover in energy space displays the relative energy (chemical potential) of H in different states. The gray, dark-red, and blue lines show the $\mu_H$ in fully hydrogenated graphene (CH), in metal hydride (PdH0.75), and in the H2 molecule, respectively. The pink and dark-red blocks show the range of energies of H at the catalyst and at the Pd(111) surface with the H coverage varying from 0.25 to 1 ML. The family of thin dark-blue lines corresponds to the energies of H bound to graphene.

Indeed, Cheng et al. have studied the dissociative chemisorption of molecular hydrogen and desorption of atomic hydrogen on Pt clusters and concluded that the number of adsorbed H2 increases with the increasing size of the cluster. Furthermore, they show that the binding strengths decrease with the increasing coverage, that is, the energy states available for H raise, approximately representing the increase of the chemical potential $\mu_H$ since the entropy contribution is less significant. They find that in low coverage the adsorption strengths are very large and at the saturation level are closer to the energies on a fully H-covered Pt(111) surface. In contrast, the strength of a H binding to sp2-carbon receptor is shown to increase with the greater coverage, due to its clustering and CH phase formation. This analysis reconciles the fact of spillover with too weak binding of the H to the bare substrate, by stressing the role of nucleation of condensed CH phase, which must be forming in the process of spillover on a graphene receptor, as it is more favorable than a H2 molecule. In our previous study, the catalyst per se was not considered, and the focus was on the variation of the hydrogen binding to the receptor and its thermodynamic comparison with gaseous H2.

Here we report the details of hydrogen binding to the catalyst particle, which serves as a gateway to the entire process and whose saturation is also an important aspect of spillover. Combining molecular dihydrogen gas phase, H dissolved on the catalyst, and H in the "storage phase" on the receptor, a conceptual quantitative diagram of spillover is drawn in Figure 1. On the left, the blue line marks the energy of H in its molecular form and the additional broad (also blue) range is the chemical potential of H including the entropic contribution at different gas conditions. On the right side, a family of thin dark-blue lines corresponds to the energies of H bound to graphene, which vary with the size and the configuration of the cluster island and converge to the CH phase energy. The midsection pink block shows the range of energies of H at the catalyst as computed and analyzed below. The first H2 molecule dissociates and binds to the catalyst rather strongly; and therefore, $\mu_H$ lies deep in this picture. However, the energies of the subsequent H2 binding gradually decrease, raising the $\mu_H$. For the spillover of a H to occur from the metal, the $\mu_H$ must exceed the CH state energy level shown by the gray line, before the metal cluster saturates (i.e., becomes unable to further accept new H2 molecules). The catalyst plays an important role in bringing the $\mu_H$ into this range. Possible metal-hydride phase formation imposes an additional constraint on the $\mu_H$. The former must lie above the $\mu_H$ of the receptor to avoid formation of metal-hydride before the spillover (assuming that the hydride phase would inhibit the catalytic activity). In this work, we validate this model by exploring through ab initio computations the gradual energy change of H on the catalyst to reveal how it fits between the energy on the receptor and as free gas. Comparing these $\mu_H$ values identifies the range of chemical potential favorable for the spillover. The role of catalyst saturation and binding strength of H with the reactor in bringing the $\mu_H$ in this desirable range is explored. Furthermore, to understand the first kinetic step, the barrier involved in the motion of a H atom from catalyst to receptor is computed and compared with the experimental observation.

RESULTS AND DISCUSSION

In order to get the $\mu_H$ on the metal catalyst, hydrogen uptake process of a free unsupported cluster was performed. More specifically, we consider relatively small four-atom Ni and Pd clusters as catalysts and a graphene with the H-terminated edge as receptor. The binding energy as well as the chemical potential of H2 on the metal cluster will depend upon the number of H2 attached and the relative positions of the H atoms. For example, the binding energy of the first H2 on the cluster will differ from the next H2 and so on. Addition of a H2 molecule leads to gain in the incremental energy, which approximately represents the chemical potential $\mu_{H_2}$, which is defined as

$$\mu_{H_2} = \Delta E(M_nH_m) = \left[E(M_nH_m) - E(H_2) - E(M_nH_{m-2})\right]/2$$

where $M_n$ is a metal catalyst. A comparison of the $\mu_{H_2}(m)$ in the metal cluster and in the receptor provides the number of H2 molecules required to saturate the metal cluster sufficiently to permit the spillover onto the receptor.
The geometries of the Pd₄ cluster are optimized, and among the various structures, a tetrahedron is found to be the lowest in energy. The magnetic moment (2 μ_B) and the Pd−Pd bond lengths (2.65 Å) in the Pd₄ cluster are in good agreement with the previous calculations performed by using the hybrid B3LYP exchange correlation functional, which gives a better description of the transition metals. The comparison provides an independent test of the method accuracy. For the subsequent hydrogenation of the catalyst, several symmetrically nonequivalent adsorption sites for a H₂ molecule on the cluster are considered, and their respective energies are compared. The first H₂ dissociatively adsorbs on the Pd₄ cluster (essentially forming a hydride molecule). Among the various structures of the Pd₄H₂, there are two lowest energy configurations, as was observed in the previous calculation. In one of the structures, the dissociated H atoms cap the adjacent triangular faces of the Pd₄ cluster (Figure 2a), while in the other, they bridge the Pd−Pd edges, which do not have the common Pd atom. We continued hydrogenation by subsequently adding the H₂ molecules to the ground state structure (cluster + H₂) obtained from the previous optimization. From the second H₂ onward, H₂ molecules do not fully dissociate, but rather bind to Pd₄ via Kubas type of interaction, where the H−H bonds are elongated from 0.73 Å (as in molecular H₂) to 0.84−0.87 Å. The hydrogenation was continued until the cluster stopped to adsorb any further H₂, that is, no bound stable configuration could be found. The Pd₄ cluster saturates after adsorbing nine H₂ molecules. The optimized geometries of these clusters are shown in Figure 2a. The 10th H₂ is repelled from the cluster and remains in the molecular form. This unattached H₂ lies more than 3.3 Å away from the atoms of the saturated cluster. The H−H bond length remains the same as in the molecular H₂, accompanied by almost no gain in binding energy, signaling the saturation of the cluster.

The incremental energies ΔE, which are plotted in Figure 2b, never exceed the energy of a H on a pristine graphene (not shown in Figure 2, and corresponding to the topmost thin line on the right side of Figure 1). Hence, thermodynamically spillover cannot be easily initiated on a pristine graphene. The possibility cannot be completely excluded because at higher temperature due to fluctuations some of the H atoms can move to the graphene. On the other hand, the incremental binding energies do exceed the chemical potential of H in the hydrogenated phase, after the adsorption of the sixth H₂ molecule, as shown in Figure 2b (the gray line there corresponds to the thin gray line in Figure 1, as well). Therefore, the spillover to the fully hydrogenated phase is indeed thermodynamically favorable after the catalyst has adsorbed six H₂ molecules.

Due to computational limitations, we use a small cluster to model the catalyst, but the qualitative conclusions on spillover are quite general. Although we believe that the overall chemisorption behavior of catalyst does not change much with increasing size, some additional complications may appear. Among them could be possible bulk metal-hydrside phase formation. In order to assess this, we have separately calculated chemical potential of H in the Pd-hydrside crystal (PdHₓ(0.75)) using standard periodic boundary conditions instead of cluster approach. The result is shown in Figure 1 by the red line, which lies ~60 meV above the gray CH line. Hence, in the case of Pd, the spillover will occur before formation of hydrside. The position of this line may vary for different metal catalysts, which is helpful in determining the best metal catalyst for spillover and could be further tuned/optimized by alloying. We also calculate the adsorption energy of the H on Pd(111) surface for coverage from 0.25 to 1 ML, shown by the red block in Figure 1. The adsorption energy of 0.25 ML hydrogen is 0.57 eV, only slightly higher (~0.1 eV) than that in the Pd₄. Hence, with increasing cluster size, the threshold of the spillover may decrease but not very significantly.

Additionally, in order to study the effect of different metal element catalysts on the spillover, we also carried out simulated hydrogenation of a Ni₄ cluster. The ground state geometry of the Ni₄ is found to be a tetrahedron, with the Ni−Ni bond length of 2.60 Å and magnetic moment of 4 μBs. The larger magnetic moment arises due to localized nature of the Ni 3d orbital. The Ni₄ adsorbs the first two H₂ molecules dissociatively. The cluster saturates after adsorbing the 10th H₂ molecule. The incremental binding energy exceeds the chemical potential of H in hydrogenated phase, after the adsorption of the seventh H₂ (Figure S1 in Supporting Information). Therefore, the effect of changing the metal from Pd to Ni essentially shifts the threshold of the spillover from sixth to seventh H₂ because of the more diffused nature of Pd 4d orbital compared with the Ni 3d orbital.
The overall trend in the hydrogenation of the Ni₄ cluster remains similar to the Pd₄ (Figure S1 in Supporting Information); therefore, further analysis is carried out only on the Pd₄ cluster.

The justification of considering incremental energies as chemical potential (essentially an average quantity) depends on how large the variance is in the removal energies of the different H atoms from a saturated cluster/catalyst. The energy cost to remove a H from the cluster may, in principle, differ with the type/position of the removed atom. In order to evaluate this, we have calculated the removal energies of the five symmetrically nonequivalent H atoms including Kubas and dissociated from fully saturated Pd₄H₁₈ as shown in Figure 2b, inset. The difference in removal energies of the five nonequivalent atoms lies within 70 meV, which is relatively small. This energy difference is within 15% of the total range of chemical potential of H on a catalyst and is reasonable enough to justify its use as a chemical potential. This difference is expected to decrease with the increasing size of the catalyst.

Moreover, the bonding strengths of the Kubas type H atoms are similar to the dissociatively adsorbed H atoms, indicating that any atom could potentially participate in the spillover process as long as μᵣ of the system has reached high enough level at overall saturation.

The above analysis shows that it is energetically possible for spillover to occur from an unsupported metal cluster to a receptor. In experiments, these clusters are supported on the substrate, and hydrogen diffuses (or rather hops) from the catalyst to the support/receptor. In order to make our model closer to the experimental situation, we next studied the hydrogenation of a supported cluster on a receptor. The pristine graphene was chosen as support as the C atoms in the vicinity of the catalyst might exhibit improved binding with the hydrogen. First, several nonequivalent sites for Pd₄ cluster on graphene have been optimized. After relaxation, however, most of the configurations converge to a structure, where three corners of the tetrahedron lie above the centers of C–C bonds (Figure 3). There are two types of Pd–Pd bond with the bond lengths of 2.60 and 2.69 Å, whereas average Pd–C bond lengths are 2.30 Å. The binding energy and the total magnetic moment of the whole Pd₄ cluster on the graphene are 0.42 eV and 1 μᵣ (reduced from the unsupported cluster), respectively.

The bonding of receptor and catalyst is analyzed by plotting the total, accumulation, and depletion of charges, shown in Figure 3b–d, respectively. The accumulation/depletion of charges is obtained by subtracting the total charges of free Pd₄ cluster and graphene calculated independently, with the same atomic position, from the total charge of the Pd₄@graphene. The positive (negative) value of the isosurface represents the accumulated (depleted) charge regions. The total charge density shows some directionality of the C–Pd bond; nevertheless, the charges around Pd are diffused, a signature of a mixed covalent and metallic bonding (Figure 3b).

Further evidence comes from the isosurfaces of accumulation and depletion, as the charge has been accumulated between the C–Pd bonds and depleted from the π-cloud of hexagonal ring in graphene (Figure 3c,d).

Next, the hydrogenation of this supported cluster was performed, following the same procedure as described above for the free cluster. Like on the free cluster, the first H₂ is adsorbed dissociatively, and subsequent ones bind via Kubas interaction. The cluster saturates with five H₂ molecules, much sooner than the free cluster. As expected, the incremental adsorption energy never exceeds the energy of a H on pristine graphene. However, it does cross the level line of C–H energy of a fully hydrogenated graphene after the adsorption of the fifth H₂ molecule, hence showing the thermodynamic possibility of the spillover. The onset of spillover occurs earlier than in the free cluster because the charge available for binding with the H₂ is now shared with the support material. This reduces the overall intake of H on the catalyst, with no harm to spillover.

Having shown the possibility of the spillover from both free and supported cluster, we turn to the kinetics aspects, which essentially involve the motion of the H atom from the metal to the receptor. The likelihood of a H atom to hop from the catalyst to the pristine graphene substrate was tested in a computational experiment by removing the H atom from the saturated catalyst and bringing it to the receptor. Upon relaxation, H goes back to the catalyst spontaneously. When the removed hydrogen is placed farther away from the catalyst, it remains attached but the whole process is rather endothermic, highlighting again the difficulty of spillover on pristine graphene. Similarly, we tested a H atom hopping to the receptor in the vicinity of a fully hydrogenated graphene phase, which was represented by hydrogenated ring hexagon near the catalyst. In this case, the H atom removed from the catalyst is more stable on the hydrogenated phase: unlike in the priss-
tine graphene case, the H does not come back to the catalyst, and the overall process becomes energetically favorable by 0.15 eV, making spillover possible on hydrogenated graphene.34

Although it is more favorable for H to be in the hydrogenated phase than on the saturated catalyst, there are still barriers involved for the motion of the H. The migration barrier for H to move from the metal to CH phase is calculated using nudged elastic band method36 (Figure 4). The barrier is $E_b = 0.68$ eV, which can be overcome even below the room temperature. Indeed, at $k_B T = 0.025$ eV, the characteristic time $\tau$ of this step can be estimated from standard rate theory37 as $\tau^{-1} = (k_B T / h) \cdot \exp(-E_b / k_B T)$. With the prefactor $k_B T/h = 10^{13}$ s$^{-1}$, one obtains $\tau \approx 30$ ms—a reasonably fast stage.34 Therefore, spillover is both thermodynamically favorable and kinetically feasible under the ambient conditions.

CONCLUSIONS

In summary, we have shown the thermodynamic and kinetic plausibility of the spillover process. Energetically, it is possible for spillover of H to occur from a metal cluster to the hydrogenated graphene, both from the free-standing and from the receptor-supported clusters. Importantly, the process does not require full saturation of the cluster because thermodynamic spillover becomes favorable even before a cluster saturates. Furthermore, it is energetically unfavorable for the spillover to occur on pristine graphene surfaces, yet a phase of hydrogenated graphene facilitates the process by significantly improving the C–H binding. The migration barrier for hydrogen from the metal cluster to the hydrogenated phase is small, suggesting that the spillover can easily occur below room temperature. These findings are in agreement with the recent experiments, where H uptake via the spillover increases with the temperature and the reduction of the substrate.38 Moreover, this work provides possibly the first explanation of the “nano-thermodynamics” of spillover and also hints toward finding materials where it can be achieved more effectively. Along with the catalyst saturation, the optimum C–H bonding has emerged as an important factor for the spillover. Therefore, any modification of the receptor that leads to an increase in this energy will also enhance the spillover (of course, within the reversibility limits). The incorporation of defects, curvature, and dopants is a few of the potential routes to facilitate nucleation by improving the C–H binding. For example, this has been demonstrated for graphene where the energy of hydrogenation changes drastically by Stone–Wales types of defects.39

Figure 4. (a) Fully relaxed cluster saturated with H, next to hydrogenated phase (gray area). (b) Plot of energies of intermediate images for the barrier calculation versus the reaction coordinate.

METHODS

The calculations are based on the density functional method with all-electron projected augmented wave potentials40,41 and the generalized gradient approximation of the Perdew–Burke–Ernzerhof (PBE)42 for exchange and correlation, as implemented in VASP.43,44 Gamma point is used for Brillouin zone sampling. Conjugate gradient scheme is employed to relax the geometry until the forces on every atom are less than 0.005 eV/Å. Large vacuum spaces (~15 Å) are used in supercells to minimize any cell spurious interactions. The migration barrier for a H atom is calculated using nudged elastic band method.36
